# GENETIC PERFORMANCE OF 40 DELI DURA x AVROS PISIFERA FULL-SIB FAMILIES 

A NOH*; M Y RAFII**; G SALEH** and A KUSHAIRI*

#### Abstract

A total of 40 oil palm dura $x$ pisifera progenies were planted on inland soil of the Serdang Series in Malaysia. They were evaluated for fresh fruit bunch (FFB), fruit components and agronomic traits. FFB production for the majority of the progenies was reasonably good for inland soil, ranging from 77.99 to $162.37 \mathrm{~kg} \mathrm{palm}^{-1}$ $y r^{-1}$. Analysis of variance showed no significant difference among the progenies, indicating lack of genetic variability for FFB and its components except average bunch weight (ABW). This was further supported by the low genotypic coefficient of variation (GCV), phenotypic coefficient of variation (PCV) and broad-sense heritability ( $h_{B}^{2}$ ). However, greater genetic control was observed in the fruit components and agronomic traits. For example, the genetic variation for mesocarp to fruit ( $M / F$ ) and shell to fruit $(S / F)$ ratios contributed more than $40 \%$ to the phenotypic variation of the characters. Among the vegetative traits, leaflet length (LL) and rachis length (RL) exhibited similar magnitude in their GCV to PCV contribution. The lack of variability in some of the characters in these materials may be an obstacle to future breeding and selection. Introgression with new materials from the germplasm collection will likely broaden their genetic base for future breeding and improvement.

Keywords: oil palm, Deli dura, AVROS pisifera, heritability.

## INTRODUCTION

The progress of oil palm breeding and selection in Malaysia is partly due to the joint research programmes between research centres in Malaysia and Africa since the 1950s (Hardon et al., 1976). One of the programmes was the Sabah Breeding Programme (SBP). In 1964, C W S Hartley, then a consultant to the Sabah government, initiated SBP with the aim of producing high-yielding planting materials suitable for the Sabah agroclimatic

[^0]conditions (Rajanaidu et al., 1985). Quoting Kushairi and Rajanaidu (2000), the breeding materials for the programme were acquired through exchange among four Malaysian and three African participating agencies. The Malaysian participants were Chemara, Harrison Malaysia Plantations Sdn Bhd (HMPB), Socfin and the Federal Department of Agriculture (DOA) while the African participants were the West African Institute for Oil Palm Research (WAIFOR), Unilever Nigeria and Unilever Cameroon. The exchanged materials in the programme included African tenera selections crossed with selected Malaysian Deli dura, and African dura selfs and crosses. Similarly, the African teneras were also selfed and crossed. A cross-section of the SBP materials was distributed to the participating agencies for their own use (Rajanaidu et al., 1985). The male parents used in this study were the Algemeene Vereniging van Rubberplanters ter Oostkust van Sumatra (AVROS) pisifera, derived from the progeny Sungai Pancur 540 (SP540) crossed to materials from Bangun Bandar

Experimental Station, Sumatra, Indonesia (Kushairi and Rajanaidu, 2000).

The Oil Palm Research Station (OPRS) HMPB and DOA imported oil palm materials into Malaysia from Sumatra in 1959 (Lee and Yeow, 1985). The Malaysian Agricultural Research and Development Institute (MARDI) later managed DOA's oil palm breeding materials. In 1979 when the Palm Oil Research Institute of Malaysia (PORIM) (now Malaysian Palm Oil Board, MPOB) was formed, this management was transferred to PORIM (Kushairi and Rajanaidu, 2000). Oil palm breeding and selection programmes in MPOB have been geared towards prospecting for new materials and utilizing the traditional collections of Deli dura and AVROS pisifera. Extensive studies on the performance of their DxP progenies have been carried out to identify outstanding progenies to increase oil production. In this study, 40 Deli dura x AVROS pisifera progenies were evaluated for bunch yield, bunch quality components and vegetative traits.

## MATERIALS AND METHODS

A total of 40 full-sib progenies from Deli dura x AVROS pisifera (DxP) with a standard cross (SC) were planted in Trial 0.314 at MPOB Keratong Station Malaysia in 1994 on inland soil predominantly of the Serdang Series. These DxP progenies were laid down in a randomized complete block design (RCBD) in
three replications with 16 palms per progeny per replicate. The trial was planted at 148 palms ha ${ }^{-1}$. Individual progenies were identified by the progeny code, prefixed PK (PORIM Kluang). The different dura sources were denoted as 'DS' (DS1-DS5) and the pisifera as ' P ' (P1-P11). Mean annual rainfall (from 1993-2004) was 2051.44 mm per year, ranging from 984 to 3314 mm per year. Data collection of the tenera progenies was carried out for fresh fruit bunch (FFB) yield (1998-2004), bunch quality components (19992004) and one round of vegetative measurements in 2003. The phenotypic (PCV) and genotypic (GCV) coefficients of variation for the agronomic characters were calculated using the method introduced by Singh and Chaudhary (1977). Data collection was based on individual palms and analysed using the Statistical Analysis System (SAS).

## RESULTS AND DISCUSSION

## Yield and Yield Components

Analysis of variance (ANOVA) of the 40 progenies (Table 1) showed no significant difference for FFB and bunch number (BNO) between progenies. However, a highly significant difference was detected for average bunch weight (ABW), indicating that a significant amount of genetic variability existed. The replicate $\times$ progeny $(\mathrm{R} \times \mathrm{P})$ item was also highly significant for all the traits, implying

[^1]inconsistencies in performance of the traits across replicates.

The performance of the 40 DxP progenies and one standard cross in the trial is presented in Table 2. The best performer was progeny PK1396 [0.212/268 $(\mathrm{DS} 3) \times 0.174 / 247(\mathrm{P} 1)]$ at 162.37 kg FFB palm ${ }^{-1}$ $\mathrm{yr}^{-1}$. The high FFB yield was due to high BNO of 10.62 bunches palm ${ }^{-1} \mathrm{yr}^{-1}$ and moderate ABW of 15.75 kg bunch ${ }^{-1}$. This BNO was highest among the progenies. On the other hand, PK1241 [0.212/598 (DS5) $\times 0.182 / 297$ (P9)] recorded the lowest FFB yield with only $77.99 \mathrm{~kg}_{\mathrm{pg}} \mathrm{palm}^{-1} \mathrm{yr}^{-1}$, far below the trial mean of $131.62 \mathrm{~kg} \mathrm{palm}^{-1} \mathrm{yr}^{-1}$. The low FFB yield in this progeny was due to its lowest ABW of 9.77 kg bunch ${ }^{-1}$ and low BNO of 7.50 bunches palm ${ }^{-1} \mathrm{yr}^{-1}$. PK1188 [0.212/439 (DS1) $\times 0.182 / 30(\mathrm{P} 6)]$ recorded the highest ABW at 18.12 kg bunch $^{-1}$. However, the FFB yield of PK1188 was low ( $129.41 \mathrm{~kg} \mathrm{palm}^{-1}$ $\mathrm{yr}^{-1}$ ) due to low BNO ( 7.31 bunches palm ${ }^{-1} \mathrm{yr}^{-1}$ ). It is therefore important in the selection of high-yielding palms to choose those with a medium ABW and high BNO. The test for least significant difference (LSD $\alpha=0.05$ ) indicated significant differences between progeny PK1396 and all the other progenies except PK1399 and PK1400. Progenies PK1399 and PK1400 had FFB yields of $150.24 \mathrm{~kg} \mathrm{palm}^{-1} \mathrm{yr}^{-1}$ and 155.92 kg palm ${ }^{-1} \mathrm{yr}^{-1}$, respectively.

In oil palm breeding and selection, the emphasis is on FFB and oil yields. However, yield is greatly influenced by environmental factors. This trial was laid down on inland soil of predominantly Serdang Series. Inland soils have lower fertility compared to coastal soils. Besides, the annual rainfall (in 1993-2004) of the area ranged from 984.55 to 3314.14 mm , making it marginal for oil palm growth and production in certain years. Due to these constraints, the trial mean FFB yield was relatively low ( $131.62 \mathrm{~kg} \mathrm{palm}^{-1} \mathrm{yr}^{-1}$ ). Ideally, oil palm requires about 2000 mm rainfall annually evenly distributed throughout the year. Rafii et al. (2001), in their study on a different set of 40 oil palm DxP progenies evaluated over six locations, reported that higher FFB yields were obtained at Carey Island ( 184.63 kg palm ${ }^{-1} \mathrm{yr}^{-1}$ ) and Teluk Intan ( $177.86 \mathrm{~kg}_{\mathrm{palm}}{ }^{-1} \mathrm{yr}^{-1}$ ) due to the very fertile soils and good rainfall amounting to 150 mm month $^{-1}$ in these two locations compared to Kluang ( $96.22 \mathrm{~kg} \mathrm{palm}{ }^{-1} \mathrm{yr}^{-1}$ ), which had poor soil texture (laterite soils) and Kudat ( $86.06 \mathrm{~kg} \mathrm{palm}^{-1}$ $\mathrm{yr}^{-1}$ ) due to the dry season (lasting about two months in a year).

## Bunch Quality Components

ANOVA showed highly significant differences among the progenies for all the traits: the ratios of mesocarp to fruit (M/F), kernel to fruit (K/F), shell to fruit (S/F), oil to dry mesocarp (O/DM), fruit to bunch $(\mathrm{F} / \mathrm{B})$, oil to bunch $(\mathrm{O} / \mathrm{B})$ and of
kernel to bunch (K/B), as well as oil yield (OY) and kernel yield (KY), but not for oil to wet mesocarp (O/WM) (Table 3). The results indicated substantial genetic variations existed in the progenies for these traits and the parents may be utilized for further selection and improvement. The replicate x progeny interaction was also highly significant, implying differences in the performance of the traits across the three replicates.

Data on the performance of the 40 DxP progenies and one standard cross are presented in Table 4. M/F of the progenies was excellent for the DxP progenies with a trial mean of $80.44 \%$. The highest ( $85.41 \%$ ) M/F was from progeny PK1436 and lowest (72.82\%) from PK1241 [0.212/598 (DS5) $\times 0.182 / 297$ (P9)]. The latter progeny had the lowest $\mathrm{M} / \mathrm{F}$ due to high $\mathrm{S} / \mathrm{F}$ of more than $18 \%$.

The oil palm kernel is also an oil-bearing component of the fruit. Oil extracted from the kernel is rich in lauric acid, the raw material for the oleochemical industries. $\mathrm{K} / \mathrm{F}$ of the progenies varied from $6.49 \%$ to $10.84 \%$ while that of K/B from $4.08 \%$ to $7.15 \%$. Progeny PK1272 [0.212/442 (DS1) $\times$ 0.182/308 (P11)] recorded the highest K/F (10.84\%) and K/B (7.15\%), while progeny PK1436 had the lowest K/F of $6.49 \%$ and progeny PK2436 the lowest K/B. Besides, PK1436, as mentioned earlier, also showed highest $\mathrm{M} / \mathrm{F}$ among the progenies.

The amounts of shell and kernel in an oil palm fruit directly affect the mesocarp content. The strategy is therefore to reduce $\mathrm{S} / \mathrm{F}$ and $\mathrm{K} / \mathrm{F}$ in order to get a higher content of mesocarp, the oil-bearing portion of the fruit. Overall, S/F of the progenies was low with an average of $10.82 \%$, and ranged from PK1388 [0.212/515 (DS2) $\times 0.174 / 348$ (P2)] with $7.57 \%$ to PK1241 with $18.38 \%$ (Table 4).

The trial means for $\mathrm{O} / \mathrm{DM}$ and $\mathrm{O} / \mathrm{WM}$ were $78.76 \%$ and $48.04 \%$, respectively. PK1196 [0.212/438 (DS1) $\times 0.182 / 30(\mathrm{P} 6)]$ had the highest O/DM, while PK1241 [0.212/598 (DS5) $\times 0.182 / 297$ (P9)] had the lowest. Likewise, for O/WM, PK1382 [0.212/70 (DS5) $\times 0.174 / 663$ (P4)] was the highest and PK1414 [0.212 / 435 (DS1) $\times 0.182 / 297$ (P9)] was the lowest, respectively. $\mathrm{O} / \mathrm{WM}$ is a component in the calculation of $\mathrm{O} / \mathrm{B}$ (Table 4).

F/B is an estimate of the fruit set of an oil palm bunch. Among the progenies, PK1279 had the best F/B at $69.47 \%$, while PK1321 [0.212/271 (DS3) $\times$ $0.182 / 305$ ( P 10 ) ] had the lowest $\mathrm{F} / \mathrm{B}$ of $51.43 \%$. High $\mathrm{F} / \mathrm{B}$ is a prerequisite for high $\mathrm{O} / \mathrm{B} . \mathrm{O} / \mathrm{B}$ is a derived character consisting of $\mathrm{F} / \mathrm{B}, \mathrm{M} / \mathrm{F}$ and $\mathrm{O} / \mathrm{WM}$. The trial mean for O/B was $24.91 \%$, reasonably good for DxP progenies. PK1436 showed the highest (27.20\%) and PK 1241 the lowest ( $21.23 \%$ ) O/B. PK1436 and PK1241 also showed the highest and the lowest M/F, respectively (Table 4).

Among the progenies, PK1396 [0.212/268 (DS3) $\times 0.174 / 247(\mathrm{P} 1)]$ had the highest OY of 38.32 kg

[^4]palm ${ }^{-1} \mathrm{yr}^{-1}$, equivalent to $5.7 \mathrm{tha}{ }^{-1} \mathrm{yr}^{-1}$. This is due to its above average MFW, $\mathrm{O} / \mathrm{WM}, \mathrm{F} / \mathrm{B}$ and $\mathrm{O} / \mathrm{B}$, even though the $M / F$ value was slightly below the trial mean. PK1241 had the lowest OY among the progenies at only 18.62 kg palm ${ }^{-1} \mathrm{yr}^{-1}$, equivalent to $2.8 \mathrm{t} \mathrm{ha}^{-1} \mathrm{yr}^{-1}$. This was due to its lowest values of M/F, O/DM and O/B but highest for S/F (Table 4).

Progeny PK1396 also recorded the highest KY of 9.77 kg palm ${ }^{-1} \mathrm{yr}^{-1}$, or $1.4 \mathrm{t} \mathrm{ha}^{-1} \mathrm{yr}^{-1}$, far above the trial mean of $7.07 \mathrm{~kg} \mathrm{palm}^{-1} \mathrm{yr}^{-1}$. At the other extreme, PK1436 recorded the lowest KY at $3.92 \mathrm{~kg} \mathrm{palm}^{-1}$ $\mathrm{yr}^{-1}$ or $0.6 \mathrm{t} \mathrm{ha}^{-1} \mathrm{yr}^{-1}$. This was due to its low K/F and K/B. This progeny was however excellent for M/F and O/B (Table 4).

## Vegetative Traits

ANOVA for the vegetative traits is presented in Table 5. The results indicated that all the vegetative traits were significantly different among the progenies, implying high genetic variation in these traits. The replicate x progeny item was also highly significant, again implying the inconsistent performance of the traits across the replicates.

Data on performance of the progenies for vegetative characters are shown in Table 6. Among the progenies, PK1418 [0.212/738 (DS5) $\times 0.182 / 230$ (P8)] scored the highest frond production (FP) at 28.48 fronds palm ${ }^{-1} \mathrm{yr}^{-1}$. As bunches are produced at the frond axils, the higher the number of fronds produced, the higher would be the potential for higher yield. At the other extreme, PK1358 [0.212/730 (DS3) $\times 0.182 / 305$ (P10)] had the lowest FP with 24.79 fronds palm ${ }^{-1} \mathrm{yr}^{-1}$. The trial mean for FP was 26.64 fronds palm ${ }^{-1} \mathrm{yr}^{-1}$. Significant difference $\left(\operatorname{LSD}_{0.05}=1.28\right)$ was detected between PK1418 and the other progenies.

The petiole cross-section (PCS) of the progenies varied from 22.41 to $37.84 \mathrm{~cm}^{2}$. PK1280 [0.212/546 (DS2) $\times 0.182 / 7$ (P5)] and PK1321 [0.212/271 (DS3) $\times 0.182 / 305(\mathrm{P} 10)]$ had the highest and lowest PCS, respectively. Significant differences $\left(\mathrm{LSD}_{0.05}=3.03\right)$ were detected between PK 1280 and PK 1381 and also with the other progenies (Table 6).

Rachis length (RL) may be used as a guide for the determination of planting density. With shorter RL, more palms can be planted in a unit area. PK1348 [0.212/482 (DS2) $\times 0.182 / 305$ (P10)] had the longest $(6.20 \mathrm{~m})$ and PK 1358 [0.212/730 (DS3) $\times 0.182 / 305$ (P10)], the shortest ( 4.85 m ) RL. The trial mean for the character was 5.56 m (Table 6). No significant difference ( $\mathrm{LSD} \alpha=0.20$ ) was found between PK1358 and all the other progenies, except PK1279, PK1321 and PK1379.

Leaflet length (LL) and leaflet width (LW) are used in the determination of leaf area. The ranges for LL and LW were 84.56 to 105.69 cm and 5.04 to
6.34 cm , respectively (Table 6). PK1278 [0.212/270 $(\mathrm{DS} 3) \times 0.182 / 7(\mathrm{P} 5)]$ had the longest LL ( 105.69 cm ). PK 1321, besides having the smallest PCS, had also the shortest LL ( 84.56 cm ) among the progenies. The progeny PK1280 had the widest LW $(6.34 \mathrm{~cm})$ besides being the largest in PCS. On the other hand, PK1358 which was identified as having the shortest LW (5.04 cm ) was also the lowest in FP and RL (Table 6).

Trunk height (HT) is an important factor in determining the economic life of an oil palm plantation due to the difficulties in harvesting tall palms. Trunk heights of the progenies at 9 years varied from 1.88 to 2.87 m . PK1179 [0.212/ 41 (DS1) $\times 0.174 / 498(\mathrm{P} 3)]$ had the highest HT with a height increment of $0.5 \mathrm{~m} \mathrm{yr}^{-1}$. PK1097 [0.212/ 374 (DS3) $\times$ $0.182 / 230$ (P8)] was identified as the shortest among the progenies ( 1.88 m ) with a height increment of 0.3 $\mathrm{m} \mathrm{yr}^{-1}$. Significant differences (LSD0.05 $=0.19$ ) for HT were detected among the progenies (Table 6).

Leaf area (LA) and leaf area index (LAI) of the progenies varied from 8.20 to $12.29 \mathrm{~cm}^{2}$ and from 4.85 to 7.28 , respectively. The progeny PK1280 [212/546 (DS2) $\times 0.182 / 7$ (P5)] had the biggest LA (12.29 cm ${ }^{2}$ ) and LAI (7.28), while PK1358 [0.212/730 $(\mathrm{DS3}) \times 0.182 / 305(\mathrm{P} 10)]$ had the lowest LA and LAI at $8.20 \mathrm{~cm}^{2}$ and 4.85 , respectively (Table 6).

For trunk diameter (DIA), the smallest was recorded in PK1414 [0.212/435 (DS1) $\times 0.182 / 297$ (P9)] at 0.56 m (Table 6). The progeny PK1097 [0.212/374 (DS3) $\times 0.182 / 297(\mathrm{P} 9)]$ had the biggest DIA at 0.75 m , a character that is not selected for in oil palm breeding. However, genotypes with large DIA may be a good source of timber for the future.

## Phenotypic and Genotypic Coefficients of Variation and Heritability Estimates

Genotypic coefficient of variation (GCV), phenotypic coefficient of variation (PCV) and heritability estimates are the basic tools for selection in breeding programmes. For rapid progress in breeding, the character selected must have a substantial amount of variation and heritability to provide ample scope for response to selection.

The values of PCV, GCV and broad sense heritability of the full-sib families for all the characters studied are presented in Table 7. The results show that genetic variation for yield and yield components, namely, FFB, BNO and ABW, contributed about $10.0 \%$ to $25.5 \%$ to the phenotypic variation, indicating a large environmental influence in the expression of these characters. The overall GCV for these characters was low (less than 10\%), implying a limited level of genetic variation. Broadsense heritability ( $\mathrm{h}_{\mathrm{B}}^{2}$ ) estimates for FFB and ABW were also low ( $<10 \%$ ), except ABW ( $13.0 \%$ ).

Unlike bunch yield and its components, the genetic variation for $M / F$ contributed more than $40 \%$ to the phenotypic variation (Table 7). A moderate

[^6]heritability estimate ( $\mathrm{h}_{\mathrm{B}}^{2}=41.9 \%$ ) was obtained for $\mathrm{M} / \mathrm{F}$, indicating that the character was more heritable than bunch yield and its components.

For S/F, genetic variation contributed more than $45 \%$ to the phenotypic variation, implying high genetic control of the character. This was further supported by its $h_{B}^{2}$ value of more than $41 \%$. It will therefore be an advantage to select for mother palms
with thinner shelled fruit, to obtain higher M/F and better $\mathrm{O} / \mathrm{B}$ in the progenies.

With respect to K/F and K/B, substantial genetic contribution was also recorded to the phenotypic variation, i.e. $32.7 \%$ and $31.8 \%$, respectively (Table 7). The $\mathrm{h}_{\mathrm{B}}^{2}$ for both traits were more than $20 \%$, indicating moderate genetic control of the characters.

TABLE 7. PHENOTYPIC (PCV) AND GENETIC (GCV) COEFFICIENTS OF VARIATION AND BROAD-SENSE HERITABILITY ESTIMATES ( $h_{\mathrm{B}}^{2}=2 \mathrm{t}_{\mathrm{g}}$ ) FOR YIELD AND YIELD COMPONENTS, BUNCH QUALITY AND VEGETATIVE TRAITS

[^7]There was a marked influence of the environment on the magnitude of the PCV and $h_{B}^{2}$ values for $\mathrm{F} / \mathrm{B}$ and $\mathrm{O} / \mathrm{B}$ (Table 7). This was indicated by the lower values of GCV. The $h_{B}^{2}$ for both characters were lower than $10 \%$.

For O/DM and O/WM, the characters were highly influenced by the environment with GCV values of $0 \%$ and $1 \%$, respectively (Table 7). This was further supported by the $\mathrm{h}_{\mathrm{B}}^{2}$ of $0 \%$ for $\mathrm{O} / \mathrm{DM}$ and $1.5 \%$ for O/WM.

With respect to OY and KY of the progenies, GCV contribution to PCV was $23.5 \%$ and $32.1 \%$, respectively, indicating moderate genetic control of the characters. The heritability estimates indicated similar trends, with $\mathrm{h}_{\mathrm{B}}^{2}$ for KY being $11.0 \%$ and OY being $20.7 \%$.

In general, GCV for most of the vegetative traits contributed about $19 \%$ to $47 \%$ towards the phenotypic variation (Table 7). Some of the characters had higher genetic control compared to the yield components as indicated by the higher GCV. The $h_{B}^{2}$ for vegetative traits varied from $9.1 \%$ to $43.4 \%$.

The highest GCV to PCV ratio was for LL ( $46.6 \%$ ), while the lowest was for HT (18.6\%) (Table 7). Among the vegetative traits, LL and RL had fairly good genetic control to the phenotypic variation at $46.6 \%$ and $44.1 \%$ contribution, respectively. This was further supported by $\mathrm{h}_{\mathrm{B}}^{2}$ estimates of more than $40 \%$ for both these traits. The rest of the characters, LAI, LA, PCS, LN, FP, LW and HT, had moderate to low GCV contribution to the phenotypic variation.

PCV and GCV for bunch yield in the full-sib families were low. Genetic variation contributed $10 \%$ to $26 \%$ to the phenotypic variance, with FFB ranked lowest. The $\mathrm{h}_{\mathrm{B}}^{2}$ was also low, below $10 \%$ except ABW with $12.9 \%$. The low genetic variation and heritability estimates in FFB and BNO may hinder further breeding and selection for the traits in these materials. However, further improvement can still be achieved for ABW because there was sufficient genetic variation, contributing more than $25 \%$ to the phenotypic variation and having $\mathrm{h}_{\mathrm{B}}^{2}$ of $12.9 \%$. Musa (2004) in his studies on Deli-AVROS populations found low PCV and GCV for bunch yields. In his Population 1, the PCV and GCV values were less than $10 \%$. However, slightly higher values were obtained in Population 2 with some values reaching $14 \%$. Rafii (1996) who studied 40 oil palm DxP progenies reported PCV values between $21.97 \%$ and $31.75 \%$, and GCV of less than $10 \%$ for bunch yield. His results also indicated low $h_{B}^{2}$ for all the characters studied except BNO ( $14.39 \%$ ).

Unlike bunch yield, the dura sources showed higher genetic variation for fruit quality characters such as M/F, S/F, K/F, KY and OY. Variability in these characters can be exploited for the production of higher yielding oil palm materials. OY is economically important. The trait is derived
and dependent on FFB and O/B. Beirnaert and Vanderweyen (1941) discovered a single gene that controls shell thickness. Exploitation of the inheritance of shell thickness has led to the commercialization of the DxP or tenera fruit form with high proportion of mesocarp and reduced shell content of the fruit.

Among the 40 progenies in the full-sib families in this study, PCV and GCV indicated low genetic variability for bunch quality components. Low GCV of less than $10 \%$ was recorded for $\mathrm{F} / \mathrm{B}, \mathrm{O} / \mathrm{B}, \mathrm{O} / \mathrm{WM}$, O/DM, OY, K/F and K/B. However, their PCVs were reasonably good with the majority being more than $10 \%$. Musa (2004) also reported low GCV for F/B, O/B and O/WM. Rafii (1996) found low GCV for $\mathrm{M} / \mathrm{F}, \mathrm{F} / \mathrm{B}, \mathrm{O} / \mathrm{B}, \mathrm{O} / \mathrm{WM}, \mathrm{O} / \mathrm{DM}$ and OY, but obtained reasonably good PCV values ( $>10 \%$ ) for these traits. Yong and Chan (1990) in their studies on Deli dura populations obtained low PCV for F/B, $\mathrm{O} / \mathrm{B}$ and $\mathrm{M} / \mathrm{F}$. The low GCV values may be due to repeated selection in the previous cycles. However, in their studies M/F, S/F and KY had better GCV and PCV values. The heritability estimates for these characters were also reasonably good at more than $20 \%$. Therefore, ample genetic variation for future breeding and selection.

Besides bunch yield, and bunch and fruit qualities, vegetative traits are gaining importance in oil palm breeding and selection. Palms with small PCS and short RL are preferred for high density planting that may increase yield per unit area. In this study, the dura sources 3 and 5 had the lowest PCS and RL. HT is also an important vegetative character. In oil palm, as in many other crops, height is given negative emphasis in selection. Palms with slower height increment are preferred because this may prolong the economic life of the crop and reduce the cost of harvesting. For trial 0.314 , the shortest full-sib family was PK1097, derived from DS3 (H.Estate x Elmina) with the Dumpy E206 gene. The tallest progeny, PK1179 was from DS1 (Banting x Banting). Mean trunk height of PK1097 was 1.88 m, or a height increment of $31 \mathrm{~cm} \mathrm{yr}^{-1}$, which is slower than that of the current DxP planting materials of $40-75 \mathrm{~cm} \mathrm{yr}^{-1}$ (Rajanaidu et al., 2000).

## CONCLUSION

Performance of the 40 oil palm progenies for FFB was reasonably good for materials planted on inland soil. The range in FFB yield of the full-sib DxP progenies was 77.99 to 162.37 kg palm ${ }^{-1} \mathrm{yr}^{-1}$. ANOVA showed the lack of variability in FFB and its components except ABW. This was supported by the low GCV, PCV and $h_{\text {. }}^{2}$. The best progeny PK1396 ( $0.212 / 268 \times 0.174 / 247$ ) from DS3 (H.Estate x Elmina dura) had an FFB yield of $162 \mathrm{~kg} \mathrm{palm}^{-1} \mathrm{yr}^{-1}$
and OY of $38.32 \mathrm{~kg} \mathrm{palm}^{-1} \mathrm{yr}^{-1}$, equivalent to 5.67 t $\mathrm{ha}^{-1} \mathrm{yr}^{-1}$. Best FFB yield was attributed to highest BNO (10.62 bunches palm ${ }^{-1} \mathrm{yr}^{-1}$ ) and moderate ABW ( 15.75 kg bunch $^{-1}$ ), and further augmented by O/B of $25 \%$. Overall, fruit components and vegetative traits showed higher variability compared to bunch yields. There is ample room for breeding and selection for these traits.
